

# Operation of CEBAF photoguns at average beam current $> 1$ mA

M. Poelker, J. Grames, P. Adderley, J. Brittian,  
J. Clark, J. Hansknecht, M. Stutzman

Can we improve charge lifetime by merely increasing the laser spot size? (distribute ion damage over larger area)

How relevant is CEBAF experience at 200  $\mu$ A ave current and laser spot size  $\sim 500$   $\mu$ m for operation at mA beam current?

Important questions for high current ( $> 1$  mA) photoinjectors at FELs, ERLs and proposed NP facilities like ELIC and eRHIC

Thomas Jefferson National Accelerator Facility

# Ion Backbombardment Limits Photocathode Lifetime

(Best Solution - Improve Vacuum, but this is not easy)

Can increasing the laser spot size improve charge lifetime?

But QE at  $(x_i, y_i)$  degrades more slowly because ion damage distributed over larger area (?)

# Where do ions go? Reality more complicated

High energy ions focused  
to electrostatic center

Which ions more problematic?

We don't run beam from  
electrostatic center

Ions create QE trough to  
electrostatic center

Top View:  
100 kV Load Locked Gun

## Side View: 100 kV Load Locked Gun

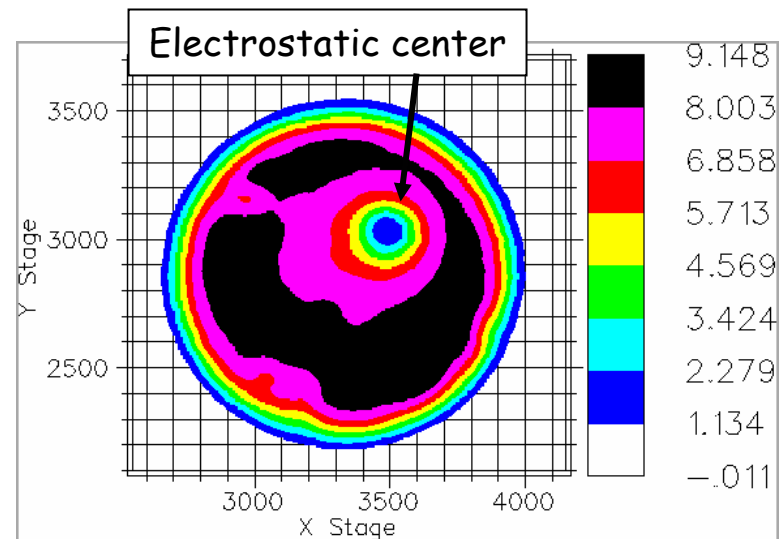

Mask to limit active area

# "QE Scan" using lens attached to stepper motor x/y stage

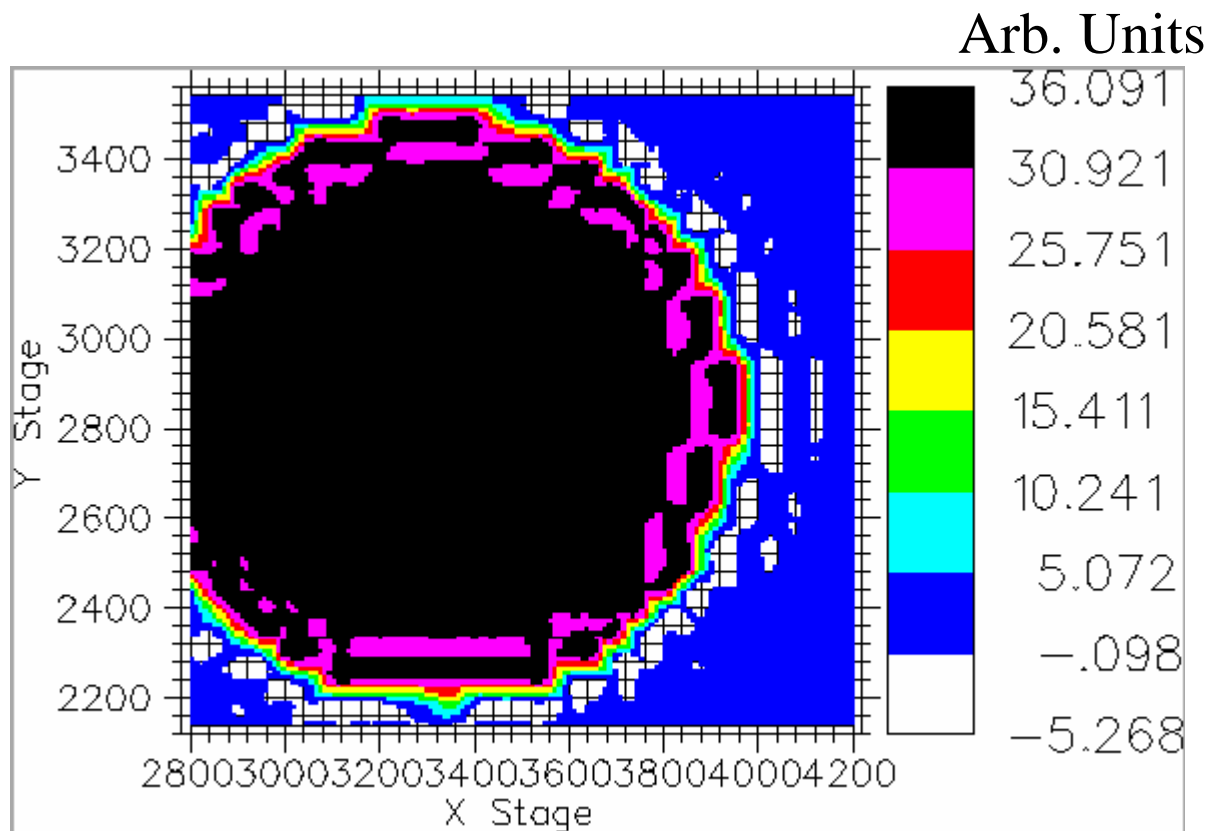

Used 5 mm hole throughout experiment

## Is 5 mm active area well suited for gun geometry?

QE scan at 100 kV indicates beam from entire photocathode delivered to dump. Gun/beamline "acceptance" seems adequate

## Experiment:

Measure  $1/e$  charge lifetime using different laser spot sizes.  
Strive to keep other operating conditions constant (e.g., orbit, position of laser spot on photocathode, starting QE, etc).

## Details:

- Green light at 532 nm, DC Beam.
- Gaussian laser spots: runs at 342 $\mu$ m, 842 $\mu$ m and 1538 $\mu$ m
- Bulk GaAs, initial max QE between 13 - 19%, 5 mm active area
- Gun vacuum w/o beam  $\sim 2 \times 10^{-11}$  Torr
- Beam dump degassed at 450C
- Beam current constant via feedback loop to laser attenuator
- Record ion pump current, laser power "pick-off" monitor.
- Charge extracted during each run between 10 - 200 C
- Five activations, one photocathode, total charge extracted 1345 C
- Ion damage restoration, typ. heat at 575C for 24 hours

A "typical" set of runs: Record ion pump current at 7 beamline locations, laser power via "pickoff" detector, laser attenuator setting, beam current at dump.

$$1/e \text{ Charge Lifetime} = \frac{\text{Charge Extracted}}{\ln (QE_i / QE_f)}$$

# 1/e Charge Lifetime versus Beam Current, 342 $\mu\text{m}$ laser spot

Fit =  $a / i^b$   
Why? Why not?  
Lifetime scales as  $1/i^b$   
where  $i$  is beam current.  
Here  $b = 1.256$

Later, we see  $b$  ranged  
from 0.2 to 1.3 for  
entire set of runs. More  
later.

Charge lifetime worse at high current. This makes sense - More electrons to ionize gas, and more gas to ionize (from beam dump and elsewhere).

# 1/e Charge Lifetime vs Beam Current: 342 $\mu\text{m}$ , 842 $\mu\text{m}$ and 1538 $\mu\text{m}$

Very little, if any, lifetime enhancement with larger laser spots

Expectation:

$$\left[ \frac{1538}{342} \right]^2 = 20.2$$

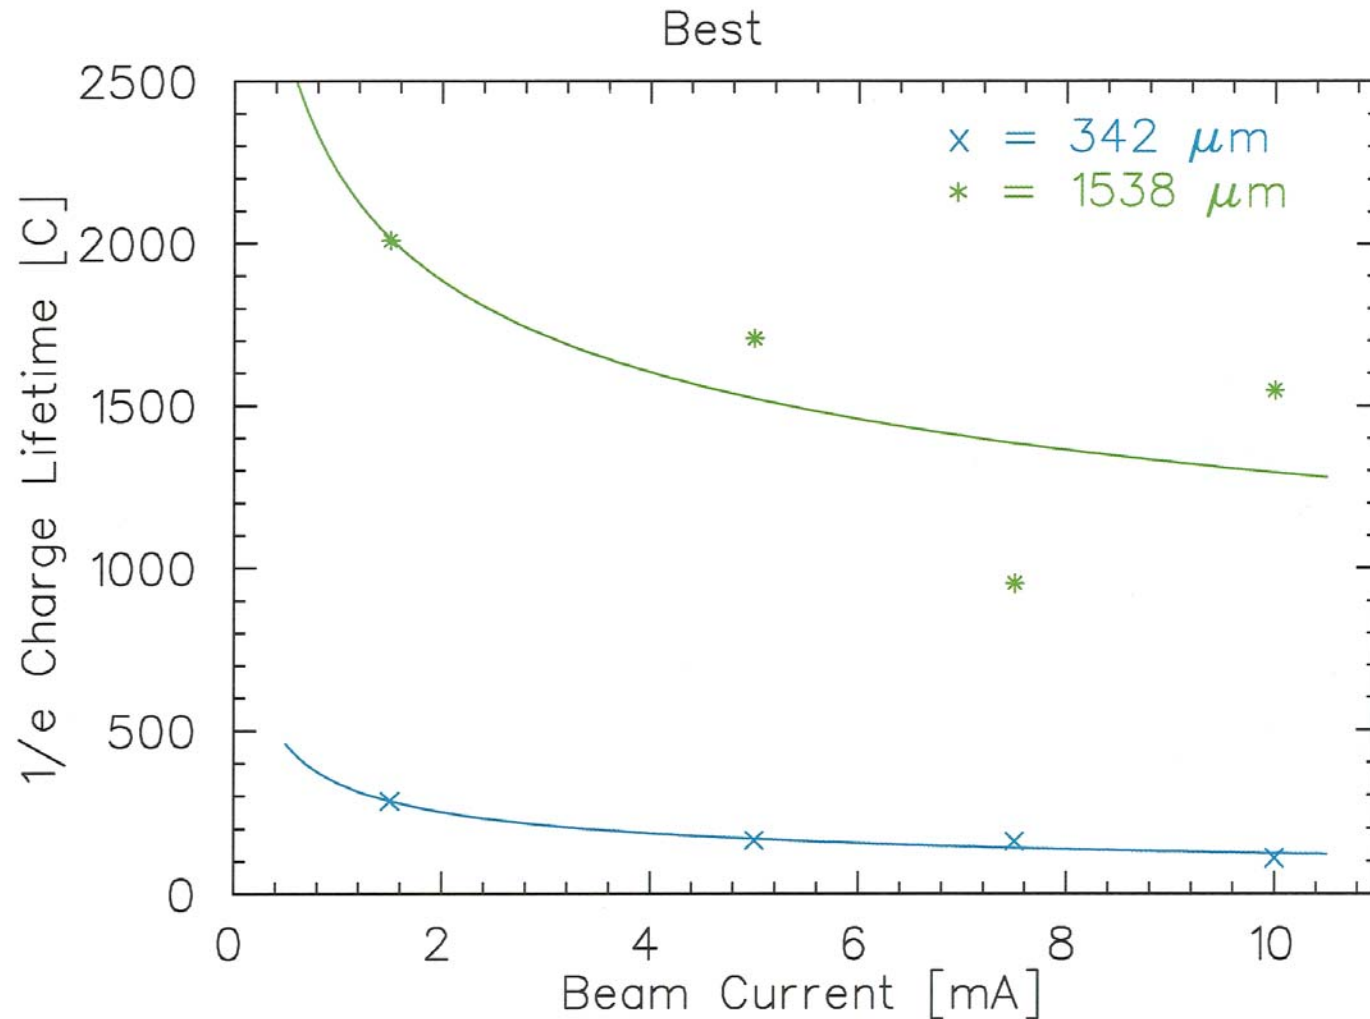

$$\left[ \frac{842}{342} \right]^2 = 6.1$$

# 1/e Charge Lifetime: 1538 $\mu\text{m}$ laser spot, from two locations

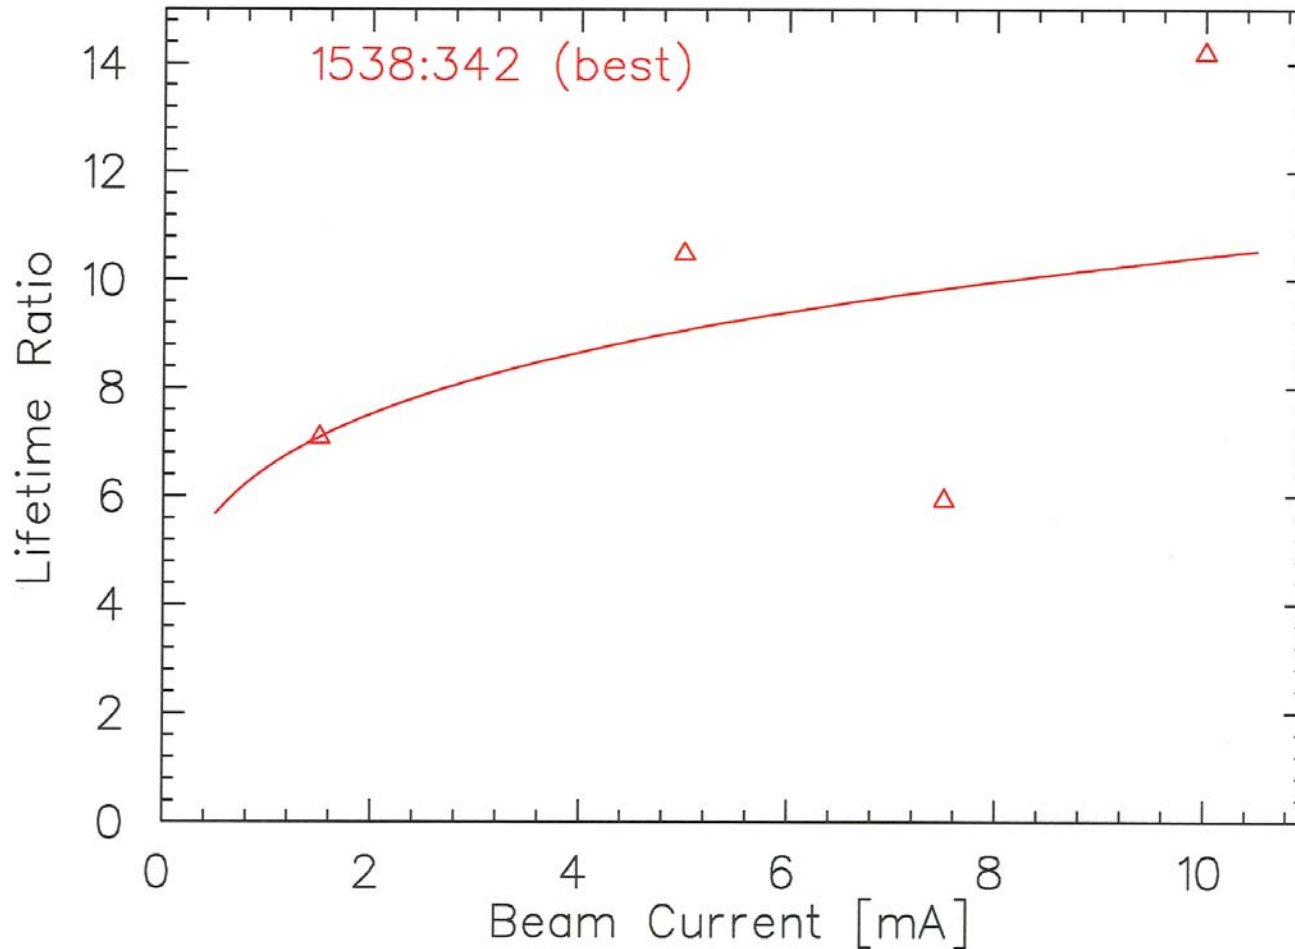

Location 2  
further from  
electrostatic  
center by  $\sim$   
400 $\mu\text{m}$

# 342 $\mu\text{m}$ and 1538 $\mu\text{m}$ laser spots from same "good" location

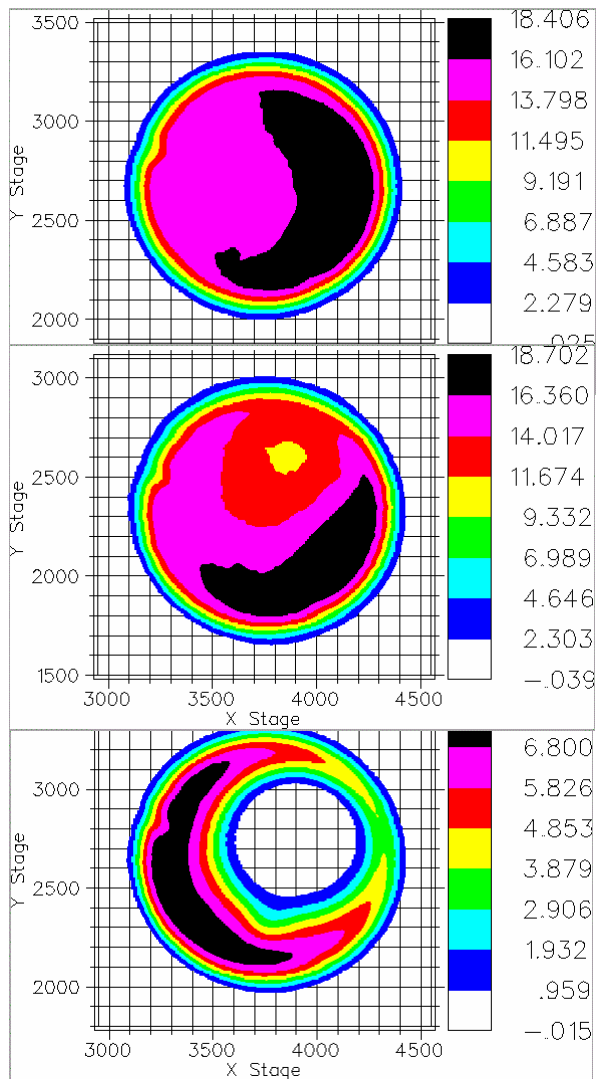

# Lifetime enhancement? YES, but not what simple picture predicts

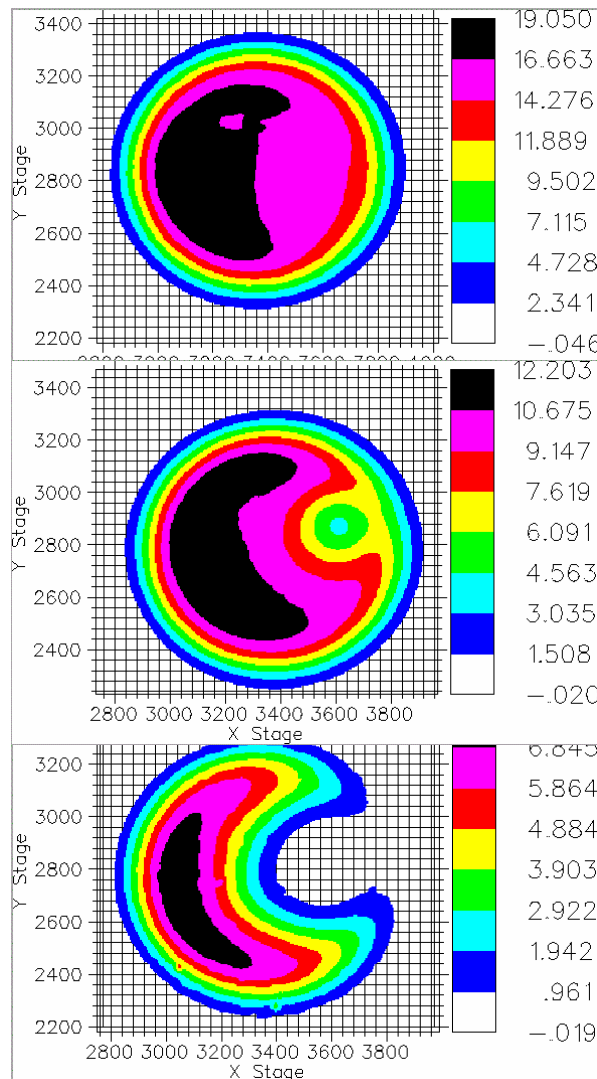

Expectation:

$$\left[ \frac{1538}{342} \right]^2 = 20.2$$

342  $\mu\text{m}$

842  $\mu\text{m}$

1538  $\mu\text{m}$

QE reduction at electrostatic center and overall

CEBAF 1/e charge lifetime similarly "random"

Charge extracted from CEBAF gun over 4 year period

Thomas Jefferson National Accelerator Facility

## "Obvious" Conclusions;

- 1) Some of the runs with 1538  $\mu\text{m}$  laser spot provided very good charge lifetime  $> 1000$  C at beam currents to 10 mA! World record?
- 2) Good evidence for lifetime enhancement using larger laser spot. (Simple scaling argument likely not valid)
- 3) Charge density lifetime numbers with 342  $\mu\text{m}$  laser spot are comparable to CEBAF numbers with high polarizaiton material.  $> 2 \times 10^5$  C/cm<sup>2</sup>
- 4) Unfortunately (for those building high current guns), good charge density lifetime not maintained at large laser spot sizes ( $\sim < 1 \times 10^5$  C/cm<sup>2</sup>)

## "Not so obvious" Conclusions;

- 1) Simple exponential decay not always appropriate
- 2) Good charge lifetime not clearly correlated to good gun vacuum (at least gun ion pump current).
- 3) (so far) it has been difficult to identify conditions that lead to long charge lifetime. Spot location on photocathode seems to be very important. Radial position: further from EC is better. But not whole story.
- 4) When using simple  $a/i^b$  fit,  $b$  ranged from 0.2 to 1.3 for entire set of runs.  $b = 1$  implies strict current dependence (OK),  $b > 1$  implies current + vacuum dependence.  $b < 1$  significant?
- 5) Where do ions go? "Beaming"? Does the potential of the beam begin to play a role? Modeling required.

Dump Ion Pump Current scales with beam current

Not obvious that gun ion pump current scales with beam current

Best charge lifetime not necessarily associated with best gun vacuum (in this case, ion pump current)
